Abstract

This study assessed the dynamics of First Birth Interval (FBI) after marriage, its determinants as well as relationship between fertility and FBI among women of reproductive age in Nigeria. We right-censored FBI of women aged 15-49 years using 2013 Nigeria DHS data, used Kaplan Meier survival function to monitor the timings and Cox Proportional Hazard (CPH) and Generalized Gamma (GG) regression to model factors affecting FBI. The median FBI in Nigeria was 1.75 years and decreased with delayed age at marriage. Women with higher education have shorter FBI (TR=0.86(95% CI: 0.85-0.88)). Urban women were more likely to have earlier FBI (HR=1.28 95% CI: 1.24-1.32)). Fertility was significantly associated with FBI. The longer the FBI the lower the fertility level and vice versa except for women aged 15-19 years. Age at marriage, educational attainment, wealth status and residence were the main determinants of timing of first birth after marriage in Nigeria.

Keywords: first birth interval, Cox proportional hazard, Generalized Gamma model, fertility.

Introduction

Across the globe, landmark reproductive events such as sexual debut, marriage, birth and pregnancy have been used by demographers to understand fertility behavior of women (Baschieri & Hinde, 2007; Kumar & Danabalan, 2006; Rasekh & Momtaz, 2007; Shayan, Mohammad, Ayatollahi, & Zare, 2014). The time interval between marriage and first birth (FBI) is prominent among the events and it could shape the reproductive characteristics and health as well as psychological of women(Kumar behavior Danabalan, 2006; Shayan et al., 2014). It might also dictate the number of children a woman will have in her reproductive cycle. In contemporary African setting and in most developing countries, families, friends and couples usually expect first births within one year of marriage, after which they become apprehensive(Feng & Quanhe, 1996). Early FBI has also been described as a way of showing that the woman is fertile (Gurmu & Etana, 2014).

Women's fertility and country's fertility level are affected by mirage of factors including availability of reliable birth control methods, religious beliefs, traditions and cultural norms, acceptability of abortion, age at marriage, infant mortality rate, educational and career development opportunities, economic factors, urbanization (Baschieri & Hinde, 2007; Kumar & Danabalan, 2006; Shayan et al., 2014). These factors could be categorized as cultural, http://aps.urnals.a

social, economic and health factors. They operate through ratio of women in sexual unions, using contraception, who are not currently fecund and the level of induced abortion (John Bongaarts, 1978; Population Reference Bureau, 2011; Suwal, 2001).

FBI may determine women's reproductive patterns (Rasekh & Momtaz, 2007) and also affect a country's fertility transitions. It is believed that women who had their first birth soon after marriage may have more births than equally fecund women who had delays. The shorter intergenerational time that results from high fertility due to short FBIs from younger women could escalate a country's population growth (Baschieri & Hinde, 2007; Kumar & Danabalan, 2006; Shayan et al., 2014).

While documented studies on FBI abounds in some parts of Africa (Baschieri & Hinde, 2007; Gurmu & Etana, 2014) and also in the Middle East (Kumar & Danabalan, 2006; Shayan et al., 2014) and in other parts of the world, such studies are relatively scarce in Nigeria. The study of marriage to first birth among women in Nigeria is crucial in ensuring better understanding of the dynamics of one of the determinants of population growth and to inform policy makers so as to channel appropriate efforts at controlling this major player in population growth. The burning question are: What is Nigeria's FBI? What are the factors affecting timing of first birth

after marriage in Nigeria? What are the magnitudes of these effects in the presence of a censored data?

The primary aim of this paper is to examine the dynamics and factors that determine the interval between marriage and first birth and the interplay between this factors in the Nigerian context. Secondarily, we investigated relationship between timing of marriage and offered explanations attributing such relationships. Besides documenting up to date information on dynamics and determinants of FBI in Nigeria, this study assessed the relationship between FBI and fertility among women. Unlike in most studies on FBI, which excluded married women without births, this current included all married women who participated in the survey as they all have inherent chances of giving births sometimes during their marriages. The information from both categories of women were used to arrive at our conclusions and the recommendations we made.

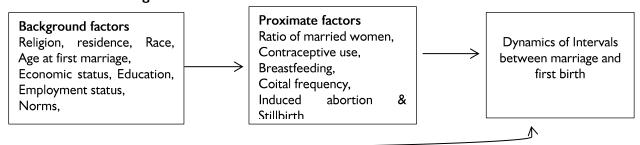

Literature review and Theoretical Framework

Demographic and socio-economic factors including mothers' education, residence, age at marriage, knowledge and use of contraceptives, employment status have been identified to influence FBI. These factors also include other socio-cultural factors such

as race, values and norms (Baschieri & Hinde, 2007; Feng & Quanhe, 1996; Kumar & Danabalan, 2006; Rasekh & Momtaz, 2007; Shayan et al., 2014; Suwal, 2001). Education was found to have impacted FBI substantially with women having lower or no educational attainment to have births sooner than others(Feng & Quanhe, 1996; Kumar & Danabalan, 2006; Rasekh & Momtaz, 2007; Rindfuss & Hirschman, 1980; Rindfuss & John, 1983; Shayan et al., 2014). Nevertheless, a recent Ethiopian study has reported otherwise(Gurmu & Etana, 2014). The age at marriage has been identified as a determinant of timing of first births (Adebowale, Yusuf, & Fagbamigbe, 2012; Feng & Quanhe, 1996; Gurmu & Etana, 2014; Singh, Singh, & Narendra, 2010). Younger women often make reproductive decisions that could shorten FBI and other intervals and thereby increase fertility(Rasekh & Momtaz, 2007).

However, Trussell et al (1985) in their study on "determinants of birth-interval length in the Philippines, Malaysia, and Indonesia: A hazard-model analysis" found that these factors do not have any independent effect on the birth intervals; rather, they influence fertility through proximate determinants of the birth interval such as breastfeeding, contraceptive use, coital frequency and induced abortion as illustrated in Figure I (Trussell et al., 1985).

Figure 1: Theoretical and Empirical relationship between socio-demographic and other factors and Intervals between marriage and first birth

This theoretical and empirical relationship is intuitive as contraceptive use and its length of use play a critical role in FBI and fertility in general (Feng & Quanhe, 1996). Other theories of fertility and other fertility determinants models have documented the role of contraceptive use in fertility outcomes (). Bongaarts & Feeney, 2006; John Bongaarts, 1978). Rural-urban differentials in respondents' place of residence also affected FBI, the higher development level of the region where a woman lives, the wider the FBIs(Gyimah, 2008). However, the reverse could be the case as argued in an Indian study(Kumar & Danabalan, 2006). The study cited fertility behavior of a woman who lives in rural area and her husband staying in urban area to make ends meet. The authors opined that such a woman is likely

to have a prolonged FBI. This position was supported by findings of Ethiopian study which found a shorter FBI among urban women than rural women(Gurmu & Etana, 2014). Cultural practices and social custom could also significantly affect marriage to FB. Certain culture which requires the woman to spend some time with either her parent or husband's parents after marriage could lead to postponement of first births (Gurmu & Etana, 2014; Kumar & Danabalan, 2006).

The analyses in this study was therefore hinged on the Trusell's theoretical and empirical relationship between socio-demographic and other factors intervals between marriage and first birth. To determine the FBI in this study, we linked the individual women's social and background characteristics to FBI through the proximate factors.

The background characteristics were applied but the secondary nature of the data used for this study restricted us to using responses on haven had a pregnancy terminated and haven used something to prevent pregnancy as a proxy for contraceptive use. Controlling fertility in Nigeria with FBI as a tool may check her population growth and improve her health outcomes. While the less developed countries accounted for over 80% of the world population by 2012, its annual infant death was 79:1 compared to the developed countries.

The less developed countries, of which Nigeria is prominent, have a Gross National Income (GNI) Purchasing Power Parity (PPP) of \$1 compared with \$6 in the most developed countries. Astronomical population growth in economically less developed countries could be linked with its high fertility. The Total Fertility Rate (TFR) of 2.6 among economically less developed countries is clearly above 1.6 TFR prevalent in the most developed countries. Nigeria TFR of 5.6 exceeds the world average (2.4), Africa (4.7), sub-Sahara (5.1) and her natural increase rate of 2.6 doubled the global average of 1.2 (FMoH, 2013; National Population Commission (Nigeria) and ICF International., 2014; Population Reference Bureau, 2012).

In this study we hypothesized that due to improved education coverage in the country(Ashir, Doctor, & Afenyadu, 2013; Doctor, Bairagi, Findley, & Helleringer, 2011; FMoH, 2013; National **Population** Commission (Nigeria) and **ICF** International., 2014; National Population Commission (Nigeria) and ICF International, 2009), the FBI will be shorter among the better educated as higher educational attainment often increase age at first marriage(Adebowale, Fagbamigbe, Okareh, & Lawal, 2012; FMoH, 2013; National Population Commission (Nigeria) and ICF International., 2014). However there could be interplay between education and other social changes such as marriage system, employment, sexuality, family planning etc. We also hypothesized that there is no association between women's FBI and number of children ever born. We controlled for the effects of individual woman's characteristics on a possible dependence between FBI and of timing of first marriage and make recommendations that could lower fertility in Nigeria.

Data Sources and Methods Study design and setting

We used the 2013 NDHS(National Population Commission (Nigeria) and ICF International., 2014) data to answer questions surrounding FBIs among women in Nigeria. The cross-sectional and nationally representative data provided up to date information

about demographics and fertility of women of reproductive age in Nigeria. It engaged a four-stage sampling procedure. First stage was selection of local government areas on rural-urban basis from every state and the Federal Capital Territory (FCT), then selection of clusters, selection of households and lastly the selection of the individuals. The individuals were administered the pre-tested semi-structured questionnaires by well-trained interviewers and field supervisors during face-to-face interviews. A total of 38948 women age 15-49 were successfully interviewed. Written informed consent was given by participants for their clinical records to be used in the study.

Data

The respondents provided information on their background characteristics (age, religion, education etc.), reproductive history (time interval between marriage and first birth, age at first marriage and age at first birth) and children mortality, knowledge, source, and use of family planning methods. In this study, we defined marriage as any form of formal or informal consensual cohabitation between a man and woman (Measure DHS, 2011). Engaged partners were excluded in the analysis. We used time interval between marriage and first birth (FBI) as the dependent variable while geographical zones of residence, education, religion, residence, age at first marriage, husband education, type of family, age difference between husband and wife, if respondent ever had a terminated pregnancy or not and whether she has ever used something to prevent pregnancy used as independent variables. We dropped ethnic affiliation in the analysis as it was found to have strongly collinerity with religion affiliation and geographical zones of the women. Our choices of variables were based on the theoretical framework documented in Trusell et al (1985) and the findings in some previous studies (Adebowale, Yusuf, et al., 2012; Feng & Quanhe, 1996; Gurmu & Etana, 2014; Singh et al., 2010). Among the 38948 women who participated in the 2013 NDHS, 9820(25.2%) who were never married, 871(2.2%) living with nonmarital partners, 1977(7.1%) who had births before marriage and 3587(13.4%) who were pregnant before marriage (they reportedly had their first child before ninth month of marriage) were excluded from further analysis. Included in the analysis were the 22888 women who were married and either had first births after 8th month of marriage (89.9%) or who have had no birth (10.1%). We grouped FBI into 3 categories: before 1.5 years, 1.5-2.9 years and 3 years or thereafter as used in an Iranian study(Rasekh & Momtaz, 2007).

Rationale for use of survival analysis

Following up reproductive events in the life of a although retrospectively, follows fundamental principle of survival analysis. Survival analysis describes time duration to occurrence of an event of interest. Usually a follow up study might come to an end without every participant experiencing the event of interest such as first births after marriage been studied. Also, some participants might have been lost to follow up or probably withdrew from the study. The event of interest is said to be censored among these groups of participant and are included in the analysis. This is quite understandable because any of them could experience the event of interest immediately after the study or much longer. Their inclusion will overcome systematic bias as these participants could possess unique characteristics that could better explain the outcome of interest. In this study, the populations at risk are married women who had either given birth after marriage or who are likely to give birth at any time.

Survival analysis requires the survival time and censoring index to be well defined. In this study, we created a variable "censoring index" and coded it as "I" for those who had births and "0" for those who have not. The "survival time" among those who have not given birth is the time period between their dates of marriage and interview while time interval between marriage and first births were survival times for those with births. The survivor function S(t) and hazard function h(t) were used to determine the probability that a woman "survives" longer than some specified time t before having a first birth and the instantaneous potential per unit time to have a first childbirth, given that the individual had not had a up to time t. Survival and hazard function are mathematically denoted by

$$s(t) = S'(t) = \frac{d}{dt}S(t) = \frac{d}{dt} \int_{t}^{\infty} f(u) du = \frac{d}{dt}[1 - F(t)] = -f(t).$$
 and
$$\lambda(t) = \lim_{dt \to 0} \frac{\Pr(t \le T < t + dt)}{dt \cdot S(t)} = \frac{f(t)}{S(t)} = -\frac{S'(t)}{S(t)}.$$
 (2)

In contrast to the survivor function (s(t)), which describes the probability of not experiencing the event of interest before time t, hazard function (h(t)) addresses the failure rate at time t among those individuals who have not experienced the event at time t. Hazard function measures the potential for the event to occur at a particular time t, given that the event did not yet occur. Larger values of the hazard function indicate greater potential for the event to occur.

We used Kaplan-Meier estimator, developed for scenarios where survival time is measured on a continuous scale whereby only intervals containing an event contribute to the estimate, to compute the survival estimates. The Kaplan-Meier estimates of S(t) were obtained as

$$s(t) = \prod_{j=1}^{k} \frac{(n_j - d_j)}{n_j}$$
....(3)

where n_j is the number of subject observed at time t_j and d_j is the number of subject that experienced the event of interest at time t_j . The incidence rate (IR) of FBI, which is the probability that a woman would have a first birth after marriage at time t_{k+1} given that she has not had a child by time t_k , was also determined. It is the probability of first birth occurring after a particular interval (time after marriage) given that the woman has had no birth before then.

We model the determinants of FBI using the Cox Proportional Hazard (CPH) regression, developed by David Cox (Cox & Oakes., 1983). The Cox model is in terms of hazard function which gives an expression for the hazard at time t for an individual with a given specification of a set of independent variables denoted by x to predict individuals' hazard. The model assumes the relationship for one covariate where $h_o(t)$ is the baseline hazard function, x_i are the covariates and β_i are the coefficients.

$$h(t;x) = h_0(t) \exp(x\beta) \tag{4}$$

Cox regression estimates were stratified. In the stratified estimator, the hazard at time t for a subject in group i is assumed to be

$$h_i(t) = h_{i0}(t) \exp(\beta_1 x_{i1} + ... + \beta_k x_{ik})$$
(5)

The coefficients β_i indicates whether the changes in the expected duration will be statistically significant or not. The hazard ratio (HR), expressed as the exponentials of the coefficients, implies more exposure to event of interest if it is > I, HR < I means lower exposure while HR= I has no effect on the exposure. Log rank test was used to compare the survival experience between different groups under study. Variables significant in the independent Cox

regression were used in the multiple Cox regression while controlling for confounders.

We used the Generalized Gamma (GG) model, an accelerated failure time model, to check the performance of the CPH. Beside been a parametric model, it has the advantage of estimating the coefficients more precisely and enhances easier interpretation over the Cox model, a semiparametric model. In parametric models, direct effects of the explanatory variables on the survival time are easily measured through "Time Ratio" (TR) instead of hazard. For each covariate in the model, a TR>1 implies that an individual experiences the event at a later timing and vice versa. We made provision for intra cluster correlation and also weighed the data to adjust for differences in population in each state and FCT. The use of the survival analysis approach in studies involving censored data is replete in literature (Adebowale, Fagbamigbe, et al., 2012; Adebowale, Yusuf, et al., 2012; Fagbamigbe, Adebowale, & Morhason-Bello, 2015; Fagbamigbe & Idemudia, 2016; Shayan et al., 2014; Trussell et al., 1985).

We used two approaches to test the hypothesis of no association between women's FBI and number of children ever born. Firstly, we normalised the two variables because they violated normality assumptions and then used Pearson's correlation coefficient to determine strength and direction of association between the variables. Also, we evaluated the Chisquare significance of association between grouped FBI (<1.5, 1.5-2.9 & >=3 year) and number of children ever born (0, 1-2, 3-4 & 5+ births). The hypothesis were evaluated at each age of women involved in the study since fertility experience will be different at different reproductive age. Statistical significance was determined at 5% p-value. We used the Stata (version 13) statistical analysis software for all the data analysis.

Ethical Consideration

Ethical approvals for the study was sought and obtained from the Nigeria National Health Research Committee assigned **Ethics** number NHREC/01/01/2007 as earlier documented(National **Population** Commission (Nigeria) and **ICF** International., 2014). Written informed consent was given by participants before the questionnaires were administered. Also, participant's personal information were anonymized and de-identified as the data was been collected prior to analysis. Written informed consent was given by participants for their clinical records to be used in the study.

Results

The history of first births among the 20596(89.9%) women who had experienced at least a birth is shown in Table I. The median FBI was I.7 years (20 months), 2.1 years among women who married before age I5 and I.3 years among those who married after attaining age 25 years. The median FBI was I.8 and I.4 years in rural and urban areas respectively and 2.8 years among never educated women compared with I.3 years among those with higher education. All the socio demographics of the respondents as well the spouses' characteristics were significantly associated with FBI.

Overall Median Survival Time (MST) to FBI was 1.75 years (21 months) with 1.50 years in the urban areas and 1.92 years in the rural areas. Also, FBI MST was 1.33 years among women having higher education and 2.08 years among those who had no formal education, 1.33 among women who had used contraceptives and 1.92 among those who didn't. The overall incidence rate (IR) of FBI, (risk of having a birth within a unit time) was 0.35, 0.37 among women of same age with their husband and 0.29 among women older than their husband.

In the bivariate analysis, the prognostic factors identified as significant by the CPH and GG regression models were similar. The GG showed that a woman with higher education has a shorter FBI than those with no education (TR=0.86, 95% CI: 0.85-0.88) while the CPH showed that risk of first birth after marriage was higher among women with higher education by 46% than uneducated women (HR=1.46, 95% CI: 1.38-1.54). The CPH showed higher risk of first birth after marriage among urban women than rural women (HR=1.28, 95% CI: 1.24-1.32) with a corresponding TR of 0.94, 95% CI: 0.93-0.94) in the GG model (Table 2).

We present the patterns of the survival functions of FBI for the various factors considered in this study using the Kaplan Meier methods of survival estimation in Figure 2. The survival curves of respondents' FBI across the characteristics considered appeared similar but were found to be significantly different using long rank tests (p < 0.05).

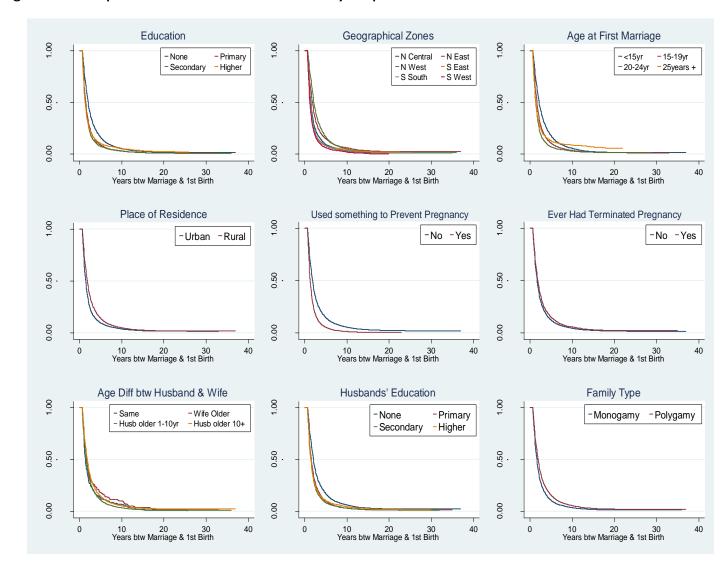

Figure 1: The Kaplan Meier survival functions of FBI by Respondents' characteristics

We fitted two models to control for the effects of the independent (background and proximate) factors in determining FBI in Nigeria. Model I consists of only the characteristics of women while Model 2 consists of Model I in addition to spouses' characteristics. In Model I, based on the GG model, women from North East (TR=1.04 95% CI: 1.02-1.06) and North West (TR=1.13 95% CI: 1.11-1.15) had a prolonged first birth after marriage compared to those from the North Central while those from the South East (TR=0.97 95% CI: 0.95-0.99) and South West (TR= 0.95 95% CI: 0.93-0.98) had a shorter FBI than in the North Central. This is similar to outcomes of the CPH model where women in North East and North West had higher risk of first birth after marriage than women in the North Central by 12%, (HR=0.88, 95% CI: 0.84-0.93) and 20% respectively compared to a shortened FBI in South East (10%) and South West (17%) than in the North Central. The risk of first birth after marriage decreased as women delayed marriage (HR=1.21, 95% CI:1.17-1.25). Addition of the husbands' characteristics in Model 2 did not improve the fitness of Model 1. Based on GG model, family types and age differences between spouses were insignificant (Table 3).

The chi square test of hypothesis of no association between FBI and children ever born was statistically significant at all ages of women except at age 15. Also the Pearson's correlation coefficient showed that the longer the FBI the lower the fertility level and vice versa except for women aged 15-19 years, who seemed to have higher fertility with prolonged FBI (Table 4). We found association between number of children ever born and FBI among women aged 40-44 years and 45-49 years with correlation coefficient of -0.3185 and

-0.3414 respectively. These categories of women were likely to have completed their family sizes.

Discussion

In this study, we set to assess the dynamics of FBI among women of reproductive age in Nigeria and also identified the social-cultural factors influencing it.

The results showed that the average time between marriage and first birth after marriage among Nigerian women is 1.75 years (20 months). We found the determinants of first birth interval in Nigeria include background, to social reproductive characteristics which consists women's age at first marriage, place of residence, geographical zones of residence, women educational attainment, ever use of something to prevent getting pregnant and haven terminated a pregnancy. We also found that some women have waited for 25.5 years to have a first birth while some have been in-union for 37 years without a birth. Generally, we found that the longer the FBI the lower the fertility level of women and vice versa. Relationship between FBI and fertility was strongest among women who were likely to have completed their family size. While our study have been strengthened by use of large nationally representative data, it might be limited by its crosssectional nature. Data were self-reported and this could have been affected by recall bias.

The average FBI of 1.75 years found in this study was similar to 1.65 years reported in a similar study in India (Kumar & Danabalan, 2006) but much higher than 1.4 years in 1985 among women of reproductive age in China (Feng & Quanhe, 1996). However, a recent African study reported a slightly longer FBI (1.92 years) in Ethiopia (Gurmu & Etana, 2014).

There were significant differences in median FBI across the respondents' characteristics. The median FBI decreased with delayed age at first marriage. We found women who married before attaining age 20 years to have a higher likelihood of prolonged FBI than those who married later. This was in concordance with reports of previous studies both in Africa and elsewhere (Feng & Quanhe, 1996; Gurmu & Etana, 2014; Shayan et al., 2014). This suggests that delayed marriage often start who childbearing soon after marriage so as to make up for the late entry into motherhood. Nevertheless, we found fertility to be lower among women who married late and had a shortened FBI. Health, psychological and social-cultural factors might have affected women who married early than those who delayed marriage and thereby have prolonged FBI. Poor knowledge, anxiety, discomfort and undue interference from family members could have affected the preparedness of young girls to transit to early motherhood besides having reproductive health challenges such as fistula (Gurmu & Etana, 2014). This implied that delayed marriage may help reduce fertility rates.

The influence of educational attainment on FBI found in our study is in agreement with outcomes of previous studies (Eini-Zinab & Agha, 2005; Feng & Quanhe, 1996; Gurmu & Etana, 2014; Islam, 2009; Kumar & Danabalan, 2006; Logubayom & Luguterah, 2013; National Population Commission (Nigeria) and ICF International., 2014). The studies have also reported prolonged FBI among women with low or no education than among respondents with higher education. The relationship between educational attainment and FBI is strong but indirect. The higher the educational attainment by married women the lower the FBI. This could be attributed to the fact that women with better education are more ready for marriage, better informed and also have better chance of choosing marriage partners which makes them to have quicker intimacy with partners and consequent shorter FBI (Gurmu & Etana, 2014).

Delayed marriage is strongly associated to longer years of education and a consequent lowered fertility. Closely related to role of educational attainment on FBI is the wealth status of the studied women on FBI. We found married women from wealthier households to have shortened FBI. The more educated a woman is, the more empowered she is through better job opportunity and a consequent better livelihood and a resultant shortened FBI and lowered fertility. Therefore, empowering women will delay first marriage and shorten FBI as well as lowering number of births.

First birth interval after marriage was more prolonged among women in rural areas than those in urban areas. The current finding is in agreement with findings of early study in Ethiopia (Gurmu & Etana, 2014) and China (Feng & Quanhe, 1996). While the Ethiopian study reported a difference of 1/4 year between rural and urban women, the Chinese study found that FBI was about 0.7 year longer for rural and coastal women as compared with upland and urban women. These differences could be ascribed to better preparedness for marriage among most women in urban areas than in rural areas and are therefore more ready for childbirth soon after marriage. Accessibility of better medical care in urban areas could have also influenced the differentials (Fagbamigbe & Idemudia, 2015a; Omo-Aghoja, Aisien, Akuse, Bergstrom, & Okonofua, 2010). The prolonged timing of first births in rural areas among women who married at a younger age and are uneducated could be ascribed to high loss of pregnancy which is commoner among this class of women as a result of poor antenatal care (Babalola & Fatusi, 2009; Lincetto, Mothebesoane-anoh, Gomez, & Munjanja, 2010).

This is intuitive because antenatal care use has been reported to be lower among less educated, poorer, younger and rural women especially from Northern part of Nigeria (Ashir et al., 2013; Doctor et al., 2011; Fagbamigbe, Akanbiemu, Adebowale, Olumide, & Korter, 2013; Fagbamigbe, Bamgboye, et al., 2015; Fatusi, 2009; FMoH, 2013; National Population Commission (Nigeria) and ICF International., 2014).

The wide difference could also be due to the fact that husbands often lives in urban cities to earn better livelihood while their wives are left behind in the rural areas thereby reducing the frequency of coitus and prolonging FBI.

In the same vein, we found geographical differences in the rate at which women have first birth after marriage. Women from the North East and North West are likely to wait 20-30% longer than the women in the Southern axis of Nigeria waited to have first birth after marriage. Our finding agreed with outcome of previous studies elsewhere (Eini-Zinab & Agha, 2005; Feng & Quanhe, 1996; Kumar & Danabalan, 2006). The situation in Northern Nigeria is understandable and anticipated. Previous studies are replete on the fact that child marriage is very prevalent in Northern Nigeria. These girls are betrothed to older men in most cases (Adebowale, Yusuf, et al., 2012; Doctor et al., 2011). They might need long time to settle down to the forced marriage and understand their husband. Often, their bodies are not fully developed for reproduction and sometimes have to stay with husband's family at the early stage of marriage. All these contributes jointly and severally to prolonged FBI. However, the influence of types and geographical distribution of residence on FBI should be interpreted with caution as the roles of proximate factors is very evident here. Essentially, the age at first marriage, level of education and women empowerment have greater influence on FBI and fertility as earlier discussed.

Women in monogamy family have higher odds of early first birth after marriage than those in polygamous family. This could be as a result of the husband having alternative woman in his life. In Nigeria setting, husbands with multiple wives rarely keep them in the same household thereby making the men to have divided attention towards the wives. This finding is at variance with an India study which found average FBI of 1.3 years among women from extended families compared to a higher 1.58 years among women from nuclear families (Kumar & Danabalan, 2006). Similarly, women who are of the same age with their husbands had a likelihood of earlier first birth after marriage than women younger or older than their husbands (Kumar & Danabalan,

2006). The wider the age difference, the longer the FBI. This could be explained by the fact that more time may be needed to develop intimacy and regular coitus between partners with wider age difference.

Respondents who had ever used contraceptives had a shorter first birth interval than those who did not. On the contrary, women who had ever experienced pregnancy termination had likelihood of longer FBI. These scenarios are understandable since most contraceptives are used to temporarily prevent pregnancy and does not cause any permanent blockage while pregnancy termination could have hindered the chance and health of another conception since such women are at higher risk of complications resulting from earlier abortion(Roger Harms, 2014; Shah & Zao, 2009) and hence a prolonged FBI. The use of family planning techniques shortened FBI and was characterised by fertility reduction.

There was strong interplay among determinants of FBI as reported in our study. It is noticeable that shorter FBI was commoner among women with higher education, urban dwellers and within highest wealth status. These are the categories of women who usually delay marriage (Adebowale, Fagbamigbe, et al., 2012; FMoH, 2013). They are thereby well prepared and ready for childbearing as soon as they get married both psychologically and financially and otherwise than other women. On the other hand, prolonged FBI has been associated with poorer women with lesser education and residing in rural areas. Considering geographical locations, FBI is more prolonged in Northern Nigeria, this is the area reputable for early girl marriage, low healthcare utilization and high health challenges among young women attending ANC(Fagbamigbe & Idemudia, 2015a, 2015b).

Conclusion and Recommendation

Age at marriage, education, residence and other socio-demographic and reproductive characteristics of a woman are the main determinants of interval between marriage and first birth in Nigeria. Although delayed first birth after marriage may help reduce fertility, the fertility of women who delayed marriage will be lower irrespective of their first birth interval. Education and other means of social empowerment will help prolong marriage, shorten FBI and hence reduce fertility. There were strong interplays among these determinants. We recommend that education and social empowerment should be used as a strategy to improve social status of women so that age at first marriage could be postponed. This approach will serve as a means of promoting cultural changes and new orientation of youths on sexual and reproductive health and hence influence timing of marriage and fertility desire that could subsequently restructure first birth interval. This is informed by the established relationship between delayed age at first marriage, shortened first birth interval and low fertility. Prolonging first birth as fertility reduction strategy among women with low education and early marriage should be embraced by the policy makers and be guided by the differentials in sociodemographic and reproductive dynamics of Nigerian women.

Contribution of Authors

AFF conceived the study, designed the study, extracted, analysed the data and wrote the results of the analyses and discussion while ESI contributed to the introduction. Both authors reviewed the final version of the manuscript.

Conflict of Interest

Authors declared no conflict of interest

Acknowledgements

We acknowledge ICF macro and the National Population Council on behalf of the Federal government of Nigeria granting us access to the data used for this study
